ABSTRACT

Low mutation and high penetrance in association with an autosomal dominance accounts to

dentinogenesis imperfecta. Both categories of dentitions such as deciduous and permanent

are affected. Important features are of mesodermal dysplasia which is observed in

histodifferentiation. Favourable prognosis can be attained by an early diagnosis and an

effective management. This heritable dentinal disorder is explained in a detailed manner in

narrative review.

KEYWORDS: Oral; dental; dentinal; inherited; anomaly.

PERSPECTIVA DEL ESPECIALISTA EN CIRUGÍA ORAL Y MAXILOFACIAL SOBRE LAS ANOMALÍAS DE LA DENTINA CENTRADAS EN LA DENTINOGÉNESIS IMPERFECTA: UNA

REVISIÓN NARRATIVA

RESUMEN

La dentinogénesis imperfecta se caracteriza por una baja tasa de mutación, alta penetrancia y

herencia autosómica dominante. Afecta tanto a la dentición decidua como a la permanente.

Una característica importante es la displasia mesodérmica, observada en la

histodiferenciación. El diagnóstico precoz y el tratamiento eficaz permiten un pronóstico

favorable. Este trastorno dentinario hereditario se describe detalladamente en esta revisión

narrativa.

INTRODUCTION

The fundamental elements of the external hard structure of a tooth, encapsulating its central portion known as the pulp, include the enamel and dentin. Cementum envelops the dentin tissue of the tooth root; however, it is categorized within the periodontal tissues (1). Dental disorders are categorized based on the impacted tissue (enamel or dentin), their nature (congenital or acquired), or the method of hereditary transmission. These conditions are further differentiated by shape and structural abnormalities, such as Amelogenesis Imperfecta or Enamel Hypoplasia, Dentinogenesis Imperfecta I, II, and III, Dentin Dysplasia type I and II, as well as various disorders like oligodontia,

hypodontia, anodontia, supernumerary teeth, and others. (1-3). Dentinogenesis Imperfecta, a well-known dental condition with a longstanding history, affects dental tissues, including both tooth enamel and dentin. Dentinogenesis Imperfecta is an inherited oral condition, initially identified by 1882 (4). The Barret in term 'dentinogenesis imperfecta' was introduced by Robert and Schour in 1939 (5). It can manifest as a primary disorder or as a component of a genetic or metabolic condition. Notably, Dentinogenesis Imperfecta is frequently observed in individuals with Osteogenesis Imperfecta. The clinical presentation of this disease is highly diverse, and a comprehensive understanding of the subject facilitates

early diagnosis and accurate assessment, particularly in the context of severe and rapidly progressing metabolic bone disorders. Recent advancements in the realms of biology and genetics have significantly facilitated the early detection Dentinogenesis Imperfecta. breakthroughs have enabled the identification of responsible genes, aiding the determination of inheritance patterns and the recognition of potential associations with other syndromes (1).

DENTINOGENESIS IMPERFECTA

Dentinogenesis Imperfecta (DI) follows an autosomal dominant mode of transmission characterized by high penetrance and a low mutation rate. This condition impacts both primary and permanent dentition, with deciduous teeth typically exhibiting

more severe manifestations(6). DI identified localized form of as а mesodermal dysplasia observed during the histodifferentiation stage (5,7). Notably, it stands out as one of the prevalent dominant disorders autosomal in humans.(7) The incidence rate of DI is reported as 1 in 8000 births in the United States.(7,8)

MAIN CLINICAL FEATURES,
RADIOGRAPHIC PRESENTATION AND
HISTOLOGICAL FEATURES OF
DENTINOGENESIS IMPERFECTA

From a clinical perspective, Dentinogenesis
Imperfecta primarily manifests through
distinct features, notably the discoloration
of the crown. The colour spectrum

Received: July 31, 2025 Accepted: September 17, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

DOI: https://www.doi.org/10.53766/AcBio/

observed in affected teeth varies, ranging from amber, yellow, brown, purple to even blue translucent hues. Concurrently, there is a notable occurrence of intense dental abrasion. The enamel tends to detach, exposing the underlying dentin, which may subsequently undergo sclerotic changes, resulting vitreous in appearance. Interestingly, many patients do not report hypersensitivity, possibly due to the protective sclerotic transformation of the dentin. However, in untreated cases, the entire dentition is at risk of abrasion up to the gingival contour. Additionally, there may be instances of pronounced mobility and premature tooth loss in advanced cases (1,5-7,9). On radiographs, the teeth exhibit bulbous molars attributed to the prominent cervical stenosis. Conical roots with periapical constrictions or even the absence of roots can be noted. The density and thickness of the enamel matrix appear typical. In the initial phases of the disease, the pulp appears unusually wide, but over time, it undergoes gradual and progressive deterioration. Pulp stones also are commonly observed in many cases (1,5-7,9). Histologically, under normal conditions, the dentoenamel junction displays a scalloped pattern, facilitating the mechanical adherence of the two tissues. Dentinogenesis Imperfecta, this In characteristic scalloping is absent, resulting in a problematic connection between enamel and dentin. Consequently, there is an early loss of enamel, exposing dentin to severe and rapid abrasion. While mantle dentin may exhibit normal characteristics,

DOI: https://www.doi.org/10.53766/AcBio/

atubular dentin showcases diminished calcification and a reduced number of odontoblasts. The dental tubules, in this appear context, coarse, sparse, irregular, with an overall decreased number (1,5-7,9-11).Also noted histologically is the irregular structure of apatite crystals. The impacted dentin contains reduced levels of calcium (Ca), phosphorus (P), and magnesium, with an elevated Ca:P ratio, and the elevated levels of water and collagen in the organic composition of dentin. (12-14)

1973, comprehensively encompasses the clinical spectrum of Dentinogenesis Imperfecta (DGI) and Dentin Dysplasia (DD) by incorporating three distinct types of DGI and two types of DD. This classification system has become integral to understanding and characterizing these dental disorders in both academic dental education and clinical application.(5,7,17)

Shields classification, implemented in

CLASSIFICATION

There are two widely recognized classification systems for Dentinogenesis Imperfecta, one developed by Witkop(8) and the other by Shields(15) (Table 1) (16).The

Dentinogenesis Imperfecta type I (DGI-I)

Clinical Features:

Dentinogenesis Imperfecta type I (DGI-I) is inherited dentin abnormality characterized by opaque dentin. With a frequency ranging from 1 in 6,000 to 1 in 8,000, it impacts both deciduous and permanent dentition.(5,7) Clinical features include the presence of abnormal dentin, affecting the structural integrity of the teeth. Additionally, DGI-I is closely associated with Osteogenesis Imperfecta (OI), establishing a significant connection between dental and skeletal abnormalities in affected individuals (1,17)

Radiographic Presentation:

Radiographically, DGI-I is identified by specific features such as opaque

dentin, which contributes to the diagnosis of this condition.(1,17)

Genetic Mutation:

DGI-I is primarily caused by mutations in the procollagen type I COL1A1 or COL1A2 gene. These genetic alterations specifically impact procollagen type I and play a crucial role in the development of abnormal dentin observed affected in individuals.(1,5,17) The genetic connection between DGI-I and OI underscores the understanding importance of the underlying genetic mutations for accurate diagnosis and comprehensive patient care. Despite this, the significant interplay between genetic disorders affecting bones and teeth, as seen in DGI-I, is not consistently explored in genetic studies. This might be attributed to historical

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

DOI: https://www.doi.org/10.53766/AcBio/

exclusions of teeth from the skeletal system, emphasizing the need for a more integrated approach to comprehensively address genetic disorders impacting both dental and skeletal. (1,17)

Dentinogenesis Imperfecta type II (DGI-II)

Clinical Features:

Dentinogenesis Imperfecta type II (DGI-II) shares similarities with DGI-I in its characteristics; the term Shields DGI-II (hereditary opalescent dentine) is employed to characterize non-syndromic autosomal dominant dentin malformations, which often mirror those found in Osteogenesis Imperfecta (OI) patients, including dental discoloration however, osteogenesis imperfecta is not a

concurrent manifestation. A distinctive trait of this syndrome includes bulbous molars, accompanied by pronounced cervical stenosis (1,5,7). Shields specified that both the primary and permanent dentitions exhibit equal clinical and radiographic involvement.(17)

Radiographic Features:

On radiographs, the presentation includes bulbous crowns characterized by pronounced cervical constriction, abbreviated roots, and pulp chambers that undergo faster obliteration than is typically observed.(17)

Genetic Mutation:

The origin of this condition can be attributed to a genetic mutation in the DSPP gene (5,7)

Received: July 31, 2025

DOI: https://www.doi.org/10.53766/AcBio/

Dentinogenesis Imperfecta type III (DGI-III)

Clinical Features:

Dentinogenesis Imperfecta Type III (DGI-III)
(Brandywine isolate hereditary opalescent dentin) bears notable resemblance to its predecessors. This particular type is of rare occurrence and has exclusively been identified within the Brandywine population in Maryland, USA. The clinical characteristics are diverse, and newly emerging teeth exhibit numerous pulp exposures. (1)

Radiographic Features:

Inclusion of shell teeth in the primary dentition is considered within this context, although it is not deemed a mandatory

characteristic. In the secondary dentitions of individuals within the Brandywine isolate, there were observations of obliterated pulp chambers, resembling radiographic features akin to DGI-II. Similarly, the permanent teeth of children who displayed shell-like teeth in their primary dentitions also exhibited radiographic similarities to DGI-II (18).

Genetic Mutation:

Shields identified DGI-III as a unique form of dentinogenesis imperfecta, possibly sharing a genetic allelic association with type II.

The mutation in the DSPP gene is a causative factor for this condition, similar to the DGI-II type. The DSPP gene, situated on chromosome 4q21, encodes the

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

IOCLÍNICA

ISSN Electrónico: 3105-403X

DOI: https://www.doi.org/10.53766/AcBio/

principal non-collagenous protein within the dentin matrix. **DSPP** undergoes protease conversion into three significant proteins—dental sialoprotein, dental glycoprotein, and dental phosphoprotein. Mutations in this gene result in reduced protein levels and/or improper DSPP calcification, contributing to insufficient dentin mineralization. Alternatively, the mutated gene accumulates in odontoblasts, causing cell destruction and impacting the protein processing rapid transport system during the production of the dentin matrix (1,5,7).

de La Dure-Molla, Foruner and Berdal (2015)

de La Dure-Molla, Foruner, and Berdal (2015) have introduced a novel classification intended to replace the Shield

Classification from 1973. This updated classification aims to address the limitations of its predecessor, particularly the clinical challenges posed by overlapping signs and symptoms within the sub-types. (19). (Table 2)

In their proposed classification, the authors advocate for the collective term "Dentinogenesis imperfecta" for DSPP (dentine sialophosphoprotein) diseases, encompassing dentinogenesis both imperfecta and dentine dysplasia. The subtypes are then differentiated based on the severity of the condition as mild, moderate and severe and radicular dentin dysplasia, although there are a few exceptions:

Shields' classification delineates
 Dentine Dysplasia type I as a distinctive
 condition characterized by exclusive

Received: July 31, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

DOI: https://www.doi.org/10.53766/AcBio/

involvement in root development. The recent classification introduces the term "radicular dentin dysplasia" to specifically designate this condition.

On the other hand, Shields'
 Dentinogenesis Imperfecta type I is

not recognized in the updated classification. The authors consider it a distinct disorder, as it is identified as a syndrome of osteogenesis imperfecta. (19)

Table 2. Former and new classification for isolated dentin rare diseases			
Shield classification of isolated	Proposed classification of isolated		
dentin diseases	dentin diseases		
Dentin dysplasia type I	Radicular dentin dysplasia		
	Dentinogenesis imperfecta		
Dentin dysplasia type II	Mild form		
Dentinogenesis imperfecta type II	Moderate form		
Dentinogenesis imperfecta type III	Severe form		

Received: July 31, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

ISSN Electrónico: 3105-403X

DOI: https://www.doi.org/10.53766/AcBio/

Mild Type:

In primary (baby) teeth, the impact is moderate, exhibiting no severe discoloration.

For permanent (adult) teeth, either no discoloration is present, or it is minimal, often manifesting as a mild grey hue.

Notably, there is minimal or no evidence of attrition (tooth wear). The crowns of the teeth may exhibit a bulbous appearance with marked constriction at the cemento-enamel junction (CEJ).(19)

Radiographically, there is observable evidence of partial pulp obliteration, characterized by a distinctive "thistleshaped appearance," as described in the literature. (19)

Moderate Type:

In the moderate type, teeth exhibit a moderate degree of discoloration, presenting hues such as blue, grey, or amber opalescent shades. Increased attrition is noticeable, leading to a reduction in crown height. The crowns may assume a bulbous appearance with noticeable constriction at the cemento-enamel junction (CEJ).(19)

Radiographically, the pulp is either notably reduced in size or completely obliterated. The roots display a thinner and shorter profile compared to the average, and there may be indications of periapical pathology.(19)

Received: July 31, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

ISSN Electrónico: 3105-403X

DOI: https://www.doi.org/10.53766/AcBio/

Severe Type:

teeth exhibit the severe type, pronounced discoloration, often appearing as a distinctive brown opalescent shade. The crowns are markedly shortened, reflecting severe attrition. Bulbous crowns prominent constriction at with the cemento-enamel junction (CEJ) are Radiographically, characteristic. а substantial pulp size is observed, accompanied by thin dentine layers, resembling what is described as "shell teeth" in the Presentation section. The roots appear thin and short, and there may be multiple periapical pathologies. (19)

This subtype replaces Shields' Dentine

Dysplasia Type I, wherein solely the roots

of the teeth are impacted. Both primary

Radicular Dentin Dysplasia:

and permanent teeth display the effects of this condition. Clinically, the teeth exhibit a normal appearance. Radiographically, there is evident root shortening, and the roots appear fused with a rounded apex.(19)

DIFFERENTIAL DIAGNOSIS

Differential diagnoses for Dentinogenesis Imperfecta, presenting similar clinical and radiographic features, encompass various conditions:(5,7,20)

- Dentin Dysplasia.
- Amelogenesis Imperfecta hypocalcified type III, resulting in enamel loss and dentin exposure.
- Internal discolorations of dental substance, including congenital

erythropoietic porphyria, rhesus incompatibility, tetracycline staining, etc.

Conditions associated with premature tooth loss, such hypophosphatasia, vitamin Ddependent Rickets syndrome, vitamin D-resistant Rickets deficiency syndrome, immune syndromes, etc.

TREATMENT

General Considerations and Management Principles:

Effectively addressing Dentinogenesis
Imperfecta (DI) involves a multifaceted
approach, encompassing the prevention of
severe attrition linked to enamel loss,
managing the rapid wear of inadequately

mineralized dentin, rehabilitating dentitions impacted by extensive wear, optimizing aesthetics, and preventing both caries and periodontal disease. The dental management strategy for DI must be tailored to the specific severity of its clinical expression.(21) Clinicians must exercise caution when treating individuals with Osteogenesis **Imperfecta** (OI), especially when undertaking surgical procedures or other treatments that could transmit forces to the jaws, thereby elevating the risk of bone fracture. Certain forms of protective stabilization may be contraindicated in patients with OI, emphasizing the need for careful consideration and a personalized approach to treatment planning. (21) Ensuring optimal preventive and restorative care is

Received: July 31, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

DOI: https://www.doi.org/10.53766/AcBio/

crucial, with aesthetics being a paramount consideration. This approach aims to maintain the patient's vertical face height when the upper and lower teeth come together. Across various types of Dentinogenesis Imperfecta (DI), the foundation of treatment remains consistent, prioritizing prevention, preservation of occlusal face height, functional maintenance, and aesthetic concerns. (1)

Preventive Measures:

Timely recognition and proactive interventions are imperative for individuals with Dentinogenesis Imperfecta (DI) to mitigate the potential adverse social and functional implications of the disorder. Regular and periodic examinations play a crucial role in identifying teeth that require

attention as they erupt. Rigorous oral hygiene practices, including calculus removal and the use of oral rinses, contribute to enhanced periodontal health. Furthermore, fluoride applications and the application of desensitizing agents have the potential to alleviate tooth sensitivity, offering additional preventive benefits.(21–23)

Restorative Care:

Routine restorative techniques prove effective in addressing mild to moderate cases of Dentinogenesis Imperfecta (DI). These procedures are more commonly employed for permanent teeth, given that the permanent dentition is often less severely affected than the primary dentition. In instances of more severe cases characterized by substantial enamel

Received: July 31, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

DOI: https://www.doi.org/10.53766/AcBio/

fracturing and rapid dental wear, the preferred treatment involves full coverage restorations for both primary permanent dentitions. The optimal success of full coverage is observed in teeth with crowns and roots that closely approximate normal shape and size, thereby minimizing the risk of cervical fracture. (24-26)Ideally, it is preferable to accomplish the restorative stabilization of the dentition before encountering excessive wear and the subsequent loss of vertical dimension. In instances where there is a notable loss of vertical dimension, there is merit in restoring a more typical vertical dimension as part of dental rehabilitation. The use of stainlesssteel crowns is advocated for primary teeth, especially when occlusal face height

may be significantly compromised due to attrition or enamel erosion.(27) Cases characterized by severe loss of coronal tooth structure and vertical dimension may be evaluated as potential candidates for overdenture therapy. Overlay dentures, applied to teeth coated with fluoridereleasing glass ionomer cement, have demonstrated successful outcomes (16). Bleaching has been documented to achieve some success in lightening the colour of Dentinogenesis Imperfecta (DI) teeth. However, since the predominant cause of discoloration stems from the underlying yellow-brown dentin, relying solely on bleaching is unlikely to result in a completely normal appearance, especially in cases of significant discoloration. (21) For aesthetic considerations, full-coverage

Received: July 31, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

DOI: https://www.doi.org/10.53766/AcBio/

crowns or veneers (composite/porcelain) are often necessary to prevent further attrition and to mask the blue-grey discolouration.(21,28) Bonding is another option, involving the application of lighter enamel on the weakened teeth. However, common cosmetic procedures like braces and bridges are generally unsuitable for Dentinogenesis Imperfecta patients, as they may exacerbate damage.

Endodontic Considerations:

Proactive measures in prevention can mitigate pulp-related pathologies, potentially facilitating less challenging endodontic procedures with improved outcomes (29).

In individuals with dentinogenesis imperfecta, some may experience

recurrent periapical abscesses, seemingly arising from pulpal strangulation secondary to pulpal obliteration or pulp exposure due to extensive coronal wear. The likelihood of periapical abscesses serves as a rationale for periodic radiographic assessments in individuals with DI(29). Root canal treatment for DI-affected teeth poses challenges due to pulp chamber and root canal obliteration or narrowing. Given pulpal obliteration there may be a need for apical surgery to preserve teeth affected by abscesses. The endeavour to navigate and instrument obliterated canals in DI teeth carries the risk of lateral perforation owing to the poorly mineralized dentin. (21) In instances of considerable attrition, overdentures may be prescribed to prevent further attrition of remaining teeth and

Received: July 31, 2025

Volumen 16, N° 32. Enero-Junio 2026 Karthik Shunmugavelu y Col. Pg. Xx-xx

DOI: https://www.doi.org/10.53766/AcBio/

maintain occlusal face height. The overarching provide goal is to comprehensive dental care that addresses both functional and aesthetic aspects, tailored the unique challenges Dentinogenesis presented bv Imperfecta.(27)

Occlusion:

Dentinogenesis Imperfecta Type I often presents with Class III malocclusion, accompanied by a notable prevalence of posterior crossbites and open bites, necessitating thorough evaluation. Given the complexity of the needs in individuals affected by DI, a multidisciplinary approach is crucial for comprehensive management. (30)

CONCLUSION

Dentinogenesis Imperfecta (DI) presents a complex spectrum of dental disorders affecting enamel and dentin. With autosomal dominant inheritance. DI demonstrates diverse clinical, radiographic, and histological features, requiring a tailored preventive, approach to restorative, and endodontic care. Recent advancements in genetic understanding offer opportunities for early detection and intervention, contributing to improved patient outcomes. A multidisciplinary approach remains pivotal for addressing the intricate needs of individuals affected by DI, emphasizing the importance of comprehensive oral health management.
